Abstract. Information-rich environments are the open environments that characterize most of the modern applications of computing technology. The applications include ubiquitous information access, electronic commerce, virtual enterprises, logistics, and sensor integration, to name but a few. These applications differ from conventional database applications not only in the nature and variety of information they involve, but also in including a significant component that is beyond the information system per se: the creation, transformation, use, and ultimate fate of information. The environments are typified only by the large amounts and varieties of information they include, and whose effective and efficient management is key to the above applications. Multiagent systems (MAS) are an important paradigm for building complex information systems, especially cooperative ones. We describe how cooperative information system architectures have evolved a set of common types of computational agents. We also describe two approaches that address complementary aspects of MAS construction.

1 Introduction

Information-rich environments are the modern, open, large-scale environments with autonomous heterogeneous information resources. They are a major target for systems based on agents and multiagent systems (MAS) technologies [6].

Numerous definitions of agents are known in the literature [3,5,10]. Indeed, the only agreement seems to be that there is a range of definitions! Some of the important properties of agents include autonomy, adaptability, and interactiveness, but exceptions reveal that an agent need not have these properties. However, we believe that agents must be capable of interacting with other agents at

the social or communicative level [4, 5]. We distinguish social or communicative interactions from incidental interactions that agents may have as a consequence of existing in a shared environment. Independently, Wegner has also argued that interaction is a key extension beyond traditional computer science [14].

1.1 Information-Rich Environments

Information-rich environments have been around for a long time. We previously defined them in broad terms as environments consisting of a large number and variety of distributed and heterogeneous information sources [5]. The associated applications are varied. They involve the purely informational ones, such as database access, information malls, workflow management, electronic commerce, and virtual enterprises. They also include the information component of physical applications, such as distributed sensing, manufacturing, transportation, energy distribution, and telecommunications. Information-rich environments have the following properties. They

- Span enterprise boundaries
- Include heterogeneous components
- Comprise information resources that can be added or removed in a loosely structured manner
- Lack global control of the accuracy of the contents of those resources
- Incorporate intricate interdependencies among their components.

Information-rich environments may often involve a significant physical or social component. However, they are amenable to specialized multiagent systems. Co-operative Information Systems are multiagent systems with organizational and database abstractions geared to open environments. Typically, a CIS includes an environment consisting of a variety of information resources, coupled with some kind of a semantic directory or ontology for the domain of interest. The semantic directory contains information about the resources, including any constraints that apply to their joint behavior. Each component of the environment, as well as its human user(s), is modeled as associated with an agent. The agents capture and enforce the requirements of their associated parties. They interact with one another appropriately, and help achieve the necessary robustness and flexibility.

Information access involves finding, retrieving, and fusing information from a number of heterogeneous sources. At the level of abstraction that concerns CIS, we are not concerned with network connectivity or the formatting variations of data access languages. Rather, our concern is with the meaning of the information stored. It is possible, and indeed common, that when different databases store information on related topics, each provides a different model of it. The databases might use different terms, e.g., employee or staff to refer to the same concept. Worse still, they might use the same term to have different meanings. For example, one database may use employee to mean anyone currently on the payroll, whereas another may use employee to mean anyone
currently receiving benefits. The former will include assigned contractors; the latter will include retirees. Consequently, merging information meaningfully is nontrivial. The problem is exacerbated by advances in communications infrastructure and competitive pressures, because different companies or divisions of a large company, which previously proceeded independently of one another, are now expected to have some linkage with each other.

The linkages can be thought of as semantic mappings between the application (which consumes or produces information), and the various databases. If the application somehow knows that employee from one database has a certain meaning, it can insert appropriate tests to eliminate the records it does not need. Clearly, this approach would be a nightmare to maintain: the slightest changes in a database would require modifying all the applications that consume its results!

1.2 Carnot

In order to best understand the work described below, it is useful to review the Carnot project, in which the authors participated. Some of the following ideas had their genesis in the experience gained with Carnot.

A number of innovations were introduced in the Carnot project—these are discussed in [13, 17]. What is most relevant here are the semantic and the distribution services. The semantic services included tools for enterprise modeling and model integration. These tools were used to generate mappings among different resources, modeled in terms of their schemas and terminologies. The mappings were based on a shared ontology for the given domain of interest [16]. The semantic services provided the basis for agent interoperation, letting the agents use models of each other’s resources in interacting in a desirable manner. This is similar in some respects to the concept of mediators [15].

The distribution services managed logical data access for both retrieval and updates. They included tools such a common interpretive execution environment as well as a distributed communicating agent facility. The distribution services handled the functionality of workflow management, in a low-level distributed computing fashion and in a high-level agent-based fashion.

Thus, Carnot used agents to provide support for relaxed, distributed, concurrent transactions across heterogeneous databases. Carnot was, however, focused on the problems of enterprise integration within a closed environment, where the component databases were known in advance and fixed.

Of the experiences gained with Carnot, two main observations apply to the enhancements needed to apply cooperative information systems in more general settings. First, although the task of semantic integration was greatly facilitated by the tools developed during Carnot, enhanced integration tools were needed to handle greater varieties of information resources made available by the web. Second, semantic integration was mostly restricted to the static aspects of the information resources, i.e., their schemas and data values, but not for their dynamic aspects, such as their processes and interactions among them. A better understanding of processes, especially as they apply in open environments, is a
prerequisite for the integration of the dynamic aspects. There has been some related work in software engineering [2], but it is mostly geared to single processes, not their interaction. This paper discusses the results we have obtained along the above two lines of thought.

1.3 Organization

Section 2 describes some components of an architecture of a multiagent system for information-rich environments. Section 3 describes the enhancements necessary to apply semantic integration to an open environment. Section 4 introduces a form of commitments that is suited to multiagent systems, shows how they can be operated on, and used to specify social policies. Section 5 applies these notions to formalize applications in electronic commerce and virtual enterprises. Section 6 concludes with a discussion of future directions.

2 Architecture

A promising approach is to the challenges of interoperability is to use mediators [15]. A mediator is a simplified agent that acts on behalf of a set of information resources or applications. Figure 1 shows a mediator architecture. The basic idea is that the mediator is responsible for mapping the resources or applications to the rest of the world. Mediators thus shield the different components of the system from each other. To construct mediators effectively requires some common representation of the meanings of the resources and applications they connect. Such a representation is called an ontology [9], and it is often managed by its own specialized agent.

It is a sign of their maturity that cooperative information systems are beginning to evolve a standard set of agent types. The resultant architecture renders development and deployment of CISs much easier, and essentially raises the abstraction level at which CISs can be described. Some of these are

User agents, which have the following characteristics:
- Contain mechanisms to select an ontology
- Support a variety of interchangeable user interfaces, such as query forms, graphical query tools, menu-driven query builders, and query languages
- Support a variety of interchangeable result browsers and visualization tools
- Maintain models of other agents
- Provide access to other information resources, such as data analysis tools, workflows, and concept learning tools.

Broker agents implement a “yellow pages” and “white pages” directory service for locating appropriate agents with appropriate capabilities. Brokers manage a namespace service, and may have the ability to store and forward messages, and locate message recipients. Broker agents also function as communication aides, by managing communications among the various agents, databases, and application programs in the environment.
Fig. 1. Typical agent architecture for a cooperative information system
Resource agents come in a variety of common types, depending on which resource they are representing, and provide the following capabilities:
- Wrappers implement common communication protocols and translate into and from local access languages. For example, a local data-manipulation language might be SQL for relational databases or OSQL for object-oriented databases.
- SQL database agents manage specific information resources
- Data analysis agents apply machine learning techniques to form logical concepts from data or use statistical techniques to perform data mining
- Resource agents apply the mappings that relate each information resource to a common context to perform a translation of message semantics. At most n sets of mappings and n resource agents are needed for interoperation among n resources and applications, as opposed to n(n-1) mappings that would be needed for direct pairwise interactions among n resources without agents (see Figure 3).

Execution agents, which might be implemented as rule-based knowledge systems, e.g., in CLIPS, are employed to
- Supervise query execution
- Operate as script-based agents to support scenario-based analyses
- Execute workflows, which might extend over the web and might be expressed in a format such as the one specified by the Workflow Management Coalition.

Mediators are specialized execution agents, which
- Determine which resources might have relevant information using help from brokers
- Decompose queries to be handled by multiple agents
- Combine the partial responses obtained from multiple resources
- Translate between ontologies.

 Ontology agents are essential for interoperation. They
- Provide a common context as a semantic grounding, which agents can then use to relate their individual terminologies
- Provide (remote) access to multiple ontologies
- Manage the distributed evolution and growth of ontologies. A common context in the form of an ontology or model of the domain can provide such semantic grounding.

Most agent-based information systems incorporate one or more agents of the above types.

3 Semantic Integration and Processing in the Large

A major task for the agents in a cooperative information system is to reconcile the varied semantics of the mostly autonomous resources in the CIS. A focus of our research in CIS is the development of tools for constructing and browsing the ontologies that serve as a basis for semantic reconciliation.
Information-rich environments include not just text and relational data, but varieties of multimedia, forms, and executable code—it has become much more complex than before. As a result, old methods for manipulating information sources are no longer efficient or even appropriate. Surprisingly, structured data has become more difficult to find and retrieve than unstructured text, because keyword searches over previously indexed documents, which can be attempted for text, are unsuitable for data. Data retrieval requires schemas, which are often unavailable, incomplete, or incomprehensible. Mechanisms are needed that allow efficient querying on diverse information sources that support structured as well as unstructured information.

Ontologies appear to be well suited for not only organizing new information, but also managing the storage and retrieval of existing information. An ontology is a model of some portion of the world and is described by defining a set of representational terms. In an ontology, definitions associate the names of entities in a universe of discourse (e.g., classes, relations, functions, or other objects) with human-readable text describing what the names mean, and formal axioms that constrain the interpretation and well-formed use of these terms. For information systems, or for the Internet, ontologies can be used to organize keywords and database concepts by capturing the semantic relationships among the keywords or among the tables and fields in a database. The semantic relationships provide users with an abstract view of an information space for their domain of interest. Ontologies are suitable for graphical representation, and can be scaled and viewed at various levels of abstraction, thereby making them suitable for large information spaces.

As an example of the tools we have been developing for exploiting the benefits of ontologies is the Java Ontology Editor, JOE [8]. JOE provides a graphical user interface for users to (1) browse and edit ontologies, or (2) construct queries based on the ontologies. By being written as a collection of Java applets, JOE can be accessed from any Java-compatible browser, and an ontology can be simultaneously viewed and edited by more than one user. This group-editing feature has the advantage that only one correct version is saved. At the same time, experts from different fields can jointly build an ontology over a length of time or, if desired, merge various small ontologies to create a single encompassing ontology. This feature is desirable in large enterprises. Examples 1 and 2 show how to browse (and edit) an ontology, and how to use it to make queries.

Example 1. Figure 2 shows JOE in its ontology browsing mode, where it is applying one of its abstraction mechanisms (a magnifier) to help users view a large ontology. The entire ontology is displayed within its main window and a magnified view of the selected area in the window on the right. JOE also an editor mode to help users modify an ontology.

Example 2. Figure 3 shows the query mode, in which users can construct queries by setting constraints on displayed attributes. The constructed query “Get the social security numbers (ssn) and the ages of all the Patients whose lastname is ‘Johnson’ and who were diagnosed with a Diagnosis named ‘cancer’ and who live
Fig. 2. JOE displaying an ontology

Fig. 3. JOE executing in the query mode
in a City named "Columbia" will be shown on a separate window to the right of
the main window. JOE will internally translate the graphical query to an SQL
statement as the user builds the query. The user can simply submit the query
by choosing the "submit" option in the "Query" menu and the results will be
displayed in a third window. JOE also provides an editor where the user, if he
or she is an expert in SQL, can directly modify or type in a new SQL statement
for execution.

4 Interaction-Oriented Programming: Commitments

We hinted above that the notion of process in information-rich environments is
much richer and flexible than in conventional settings. Indeed, traditional ab-
stractions such as database transactions are notoriously unsuited for represent-
ating and managing flexible processes. Agents are a useful metaphor, but merely call-
ing a program an agent doesn't help! We also need corresponding sophisticated
abstractions for programming the agents.

We have been pursuing a research program on Interaction-Oriented Program-
m ing (IOP) to develop and study primitives for the specification of systems of
agents and constraints on their behavior. These primitives include societies, the
roles agents may play in them, what capabilities and commitments they require,
and what authorities they grant. Agents can autonomously instantiate abstract
societies by adopting roles in them. The creation, operation, and dissolution of
societies are achieved by agents acting autonomously, but satisfying their com-
mitments. A commitment can be canceled, provided the agent then satisfies the
metacommitments applying to its cancellation.

The representations for IOP must support several functionalities, which typi-
cally exist informally, and are either effected by humans in some unprincipled
way, are hard-coded in applications, or are buried in operating procedures and
manuals. Information typically exists in data stores, in the environment, or with
interacting entities. The IOP contribution is that it

- enhances and formalizes ideas from different disciplines
- separates them out in an explicit conceptual metamodel to use as a basis for
  programming and for programming methodologies
- makes them programmable.

The notion of commitments may be familiar from databases. However, in
databases, commitments correspond to a value being declared and are identified
with the successful termination of a transaction. When a transaction terminates
successfully, it commits, but it is not around any more to modify its commit-
ments. Thus the commitments are rigid and irrevocable. If the data value com-
mited by one transaction must be modified a separate, logically independent
transaction must be executed to commit the modified value. Traditional commit-
ments presuppose that different computations are fully isolated and that locks
can be held long enough that the atomicity of distributed computations can be
assured. Although suitable for traditional data processing, for the above reasons, traditional commitments are highly undesirable for information-rich environments, where autonomous entities must carry out prolonged interactions with one another [11].

Commitments reflect an inherent tension between predictability and flexibility. Agents who can commit are easier to deal with. Also, the desired commitments serve as a sort of requirements on the construction of the agents who meet those commitments. However, commitments reduce the options available to an agent.

4.1 Commitments

We propose an alternative characterization of commitments that is better suited to agents and multiagent systems. In our formulation the commitments are directed to specific parties in a specific context. Thus an agent may not offer the same commitments to every other agent. The context is the multiagent system within which the given agents interact. An agent or multiagent system with jurisdiction over some resources and agents is called a sphere of commitment (SoCom).

A commitment is a four-place relation. The debtor refers to the agent who makes the commitment, and the creditor to the agent who receives the commitment. Commitments are formed in a context, which is given by the enclosing SoCom (or, ultimately, by society at large). Based on the above intuitions, we motivate the following logical form for commitments.

Definition 1. A commitment $C(x, y, p, G)$ relates a debtor $x$, a creditor $y$, a context $G$, and a discharge condition $p$.

4.2 Operations on Commitments

We define the following operations on commitments.

O1. Create instantiates a commitment; it is typically performed as a consequence of an agent adopting a role or by exercising a social policy (explained below).
O2. Discharge satisfies the commitment; it is performed by the debtor concurrently with the actions that lead to the given condition being satisfied.
O3. Cancel revokes the commitment. It can be performed by the debtor.
O4. Release essentially eliminates the commitment. This is distinguished from both discharge and cancel, because release does not mean success or failure of the given commitment, although it lets the debtor off the hook. The release action may be performed by the context or the creditor of the given commitment.
O5. Delegate shifts the role of debtor to another agent within the same context, and can be performed by the new debtor or the context.
O6. Assign transfers a commitment to another creditor within the same context, and can be performed by the present creditor or the context.
Through an abuse of notation, we write the above operations also as propositions, indicating their successful execution. We define some additional operations and propositions corresponding to important speech acts. These include\textit{notify} and \textit{authorize}. \textit{notify}(x, y, q) mean that $x$ notifies $y$ of $q$, and \textit{authorize}(x, y, p) means that $x$ authorizes $y$ to allow condition $p$.

### 4.3 Policies

\textit{Social policies} are conditional expressions involving commitments and operations on commitments. Policies have a computational significance, which is that they can help control the execution of operations on commitments, even without explicit reference to the context. It is their locality that makes policies useful in practice. Agents can commit to social policies just as to other expressions; in this case, the agents’ commitments are higher order, and are termed \textit{metacommitments}. An example metacommitment is \textit{cancel}(x, C(x, y, p, G)) $\Rightarrow$ \textit{create}(x, C(x, y, q, G)), which means that $x$ can cancel his commitment for $p$ if instead he adopts a commitment for $q$ (for suitable $p$ and $q$).

### 4.4 Applying Commitments

Commitments are computationally applied in the following manner. Initially, abstract SoComs are defined in terms of their \textit{roles}. Each role is associated with the capabilities it requires, the commitments it engenders, and the authorities it creates. The capabilities are the tasks the agent \textit{can} do, the commitments are what the agent \textit{must} do, and the authorities are what the agent \textit{may} do. The commitments, in particular, may be metacommitments. Indeed, they usually are metacommitments, e.g., that the agent will adopt a base commitment upon receiving a request.

At some point, possibly during execution, an agent may decide to enter into a SoCom as a particular role or roles. To do so, he would have to cause the SoCom to be instantiated from the abstract specification. To adopt a role, the agent must have the necessary capabilities, and accept the associated commitments. In doing so, he also obtains the authorities to properly play the role. The agent must then behave according to the commitments. Agents can join a SoCom when configured by humans or during execution: this requires publishing the definition of the abstract SoCom.

### 5 Designing Commitments

We consider an example in two parts. The first deals with electronic commerce; the second combines in aspects of virtual enterprises [7]. The commitments are designed based on the corresponding roles in human society.
5.1 Electronic Commerce

We first define an abstract SoCom consisting of two roles: buyer and seller, which require capabilities and commitments about, e.g., the requests they will honor, and the validity of price quotes. To adopt these roles, agents must have the capabilities and acquire the commitments. Example 3 involves two individual agents who adopt the roles of Buyer and Seller to carry out a simple deal.

Example 3. Consider a situation involving two agents, Customer and Vendor, with authority over their respective databases. The SoCom manager has an abstract SoCom for buy-sell deals with the roles of Buyer and Seller. Buyer's capabilities include asking for a price quote and placing an order. Seller's capabilities include responding to price quotes and accepting orders based on checking the inventory locally. Buyer's commitments include paying the quoted price for anything he orders. Seller's commitments include (a) giving price quotes in response to requests and (b) fulfilling orders that he has accepted.

Customer asks the manager to instantiate a deal between her (Customer) as Buyer and Vendor as Seller. The manager asks Vendor if he would like to join as Seller. When Vendor agrees, and since both agents have the requisite capabilities, capacities, and resources, the deal is set up.

Customer now wishes to check the price of a valve with a diameter of 21 mm. Upon the receipt of the query from Customer, Vendor—based on its role as Seller—offers an appropriate answer.

5.2 Virtual Enterprises

Example 4 considers a more general situation where the role of Seller is adopted by an agent who happens to be a Valvano-cum-Hoosier VE—i.e., a SoCom consisting of the hose and valve vendors. Example 5 considers the situation where the Valvano-cum-Hoosier VE detects a problem in the supply of valves for which an order has been placed. The VE automatically meets its commitments by revising the order and notifying the customer.

Now we consider the situation where one or more agents may form a cooperative SoCom or team. For simplicity, we assume that teams have a distinguished agent who handles their external interactions. We refer to this agent as the VE.

Example 4. We now consider two agents with authority over the Valvano and Hoosier databases, respectively. These agents have similar capabilities to the Seller of Example 3. They form a VE, called Valvano-cum-Hoosier VE, which can adopt the role of Seller. Buyer behaves as before and expects Seller to behave according to the buy-sell deal. However, Seller is implemented differently, with commitments among its members, which we do not elaborate here. The possible commitments of the Valvano-cum-Hoosier VE include the following.

- The VE will give price quotes to anyone who requests them.
- The VE will refund the purchase price if an order with matching valves and hoses cannot be fulfilled. There are still no refunds if an order for matching valves and hoses can be fulfilled.
– If the VE cannot fulfill an order, it will try to find an alternative order that will satisfy Customer’s requirements.

Recall that val or hos would not take refunds individually. Thus a customer might be saddled with valves for which matching hoses could not be found. However, when dealing with the VE, a customer can get a refund in those situations.

In the above examples, the actions are performed by the constituents of the SoCom. Sometimes, however, it is useful to perform actions at a higher level SoCom. Such actions are necessary when the actions of the member agents must be atomically performed or undone. Example 5 is related to this situation.

![Diagram](image_url)

**Fig. 4.** Commitment-based recovery

*Example 5.* Continuing with Example 4, suppose an order for matching valves and hoses is successfully placed. It turns out later that the valve manufacturer discontinued the model that was ordered, but recommends a substitute. The substitute valve fits different diameter hoses than the original choice. The VE knows that the original order could be satisfied using the new valve and a different set of hoses. The VE can handle this replacement itself and, based on its prior commitment, not charge the customer any extra. The customer does not need to know of the internal exchanges among the members of the VE SoCom. Figure 4 illustrates the execution.

In the above example, the discontinuation of a valve after an order for it was accepted is a kind of failure that arises after the original interaction had ended. Traditional approaches would be inapplicable in such a situation.
6 Conclusions and Future Work

Although multiagent systems have been known for a number of years and practical applications of them are spreading, they are still being built in a more or less ad hoc manner. Just as for other systems, engineering a multiagent system presupposes the existence of tools and methodologies, which in turn presuppose the existence of suitable representational frameworks and clean theories. As one would expect with MAS being a new area, the state of the art is mixed. Some problems are well-studied or there are clearer inputs from other disciplines—for these, we are seeing useful and practical tools emerging. Other problems are not as well-studied, and the inputs from related disciplines are not applicable to MAS needs, and for these the theories are still begin explored. The approaches described here can be seen as one of each kind.

The ontology tools are the culmination of several years of research and practice. They are achieving the state where they can be easily used, and by people with only minimal training in information management.

The IOP approach, of which we discussed only the aspects relating to commitments, provides a set of high-level abstractions for building systems of autonomous agents. The autonomy is essential when the underlying environment includes autonomous and heterogeneous resources. By separating out the considerations of the infrastructure, IOP promises to be a more effective and portable way of designing multiagent systems for applications such as electronic commerce and virtual enterprises.

There are some important directions for future research. Of special interest to conceptual modeling is the development of richer metamodels than we have at present. A potentially important theme is to identify useful patterns corresponding to the “best practices” in key areas, and incorporating them in our metamodels. An example area would be contracting among autonomous entities, which seems to underlie several of the upcoming open applications. Along with richer metamodels, there is need for a corresponding intuitive semantics. We have made some progress along this direction [12]. One of the themes that should be more intensively addressed is the compositionality of conceptual models. For example, one would like to build separate models for electronic commerce and virtual enterprises, and dynamically compose them to produce a model for a commercially engaged virtual enterprise. Lastly, there is a great need for expressive formal tools that support the conceptual models and their semantics.
